The sequencing of ancient DNA has enabled the reconstruction of speciation, migration and admixture events for extinct taxa¹. However, the irreversible post-mortem degradation² of ancient DNA has so far limited its recovery—outside permafrost areas—to specimens that are not older than approximately 0.5 million years (Myr)³. By contrast, tandem mass spectrometry has enabled the sequencing of approximately 1.5-Myr-old collagen type I⁴, and suggested the presence of protein residues in fossils of the Cretaceous period⁵—although with limited phylogenetic use⁶. In the absence of molecular evidence, the speciation of several extinct species of the Early and Middle Pleistocene epoch remains contentious. Here we address the phylogenetic relationships of the Eurasian Rhinocerotidae of the Pleistocene epoch^{7–9}, using the proteome of dental enamel from a *Stephanorhinus* tooth that is approximately 1.77-Myr old, recovered from the archaeological site of Dmanisi (South Caucasus, Georgia)¹⁰. Molecular phylogenetic analyses place this *Stephanorhinus* as a sister group to the clade formed by the woolly rhinoceros (*Coelodonta antiquitatis*) and Merck's rhinoceros (*Stephanorhinus kirchbergensis*). We show that *Coelodonta* evolved from an early *Stephanorhinus* lineage, and that this latter genus includes at least two distinct evolutionary lines. The genus *Stephanorhinus* is therefore currently paraphyletic, and its systematic revision is needed. We demonstrate that sequencing the proteome of Early Pleistocene dental enamel overcomes the limitations of phylogenetic inference based on ancient collagen or DNA. Our approach also provides additional information about the sex and taxonomic assignment of other specimens from Dmanisi. Our findings reveal that proteomic investigation of ancient dental enamel—which is the hardest tissue in vertebrates¹¹, and is highly abundant in the fossil record—can push the reconstruction of molecular evolution further back into the Early Pleistocene epoch, beyond the currently known limits of ancient DNA preservation.

The phylogenetic placement of extinct species relies increasingly on the sequencing of ancient DNA. Efforts to improve the molecular tools that underlie the recovery of ancient DNA have enabled the

reconstruction of approximately 0.4-Myr-old and approximately 0.7-Myr-old DNA sequences from temperate deposits³ and subpolar regions¹², respectively. However, no ancient DNA data have so far been generated from species that became extinct beyond this time range. By contrast, ancient proteins represent a more-durable source of genetic information, and have been reported¹³ to survive (in eggshell) for up to 3.8 Myr. Ancient protein sequences can carry taxonomic and phylogenetic information that is useful for tracing the evolutionary relationships between extant and extinct species^{14,15}. However, the recovery of ancient mammal proteins from sites that are too old or too warm to be compatible with the preservation of ancient DNA has so far mostly been limited to collagen type I (COL1). This protein is not an ideal phylogenetic marker, as it is highly conserved¹⁶. For example, regardless of endogeneity¹⁷, the phylogenetic placement of Dinosauria in relation to extant Aves on the basis of collagen appears to be unstable⁶. This suggests that the exclusive use of COL1 constrains deep-time molecular phylogenetics. Here we sought to overcome these limitations by testing whether dental enamel can be used as an abundant source of larger, and more phylogenetically informative, sets of ancient proteins that are preserved longer than COL1.

The archaeological site of Dmanisi (South Caucasus, Georgia) (Fig. 1a) has been dated to approximately 1.77 Myr ago by a combination of ⁴⁰Ar/³⁹Ar dating, palaeomagnetism and biozonation^{18,19}; this age represents a context that is currently considered to be outside the scope of the recovery of ancient DNA. This site has been excavated since 1983, which has resulted in the discovery—along with stone tools and contemporaneous fauna (Supplementary Table 1)—of almost 100 hominin fossils, including 5 skulls, that represent the ‘georgicus’ palaeodeme within *Homo erectus*¹⁰. These are the earliest fossils of the genus *Homo* outside of Africa.

The geology of the Dmanisi deposits favours the preservation of faunal material (see Supplementary Information), as the primary aeolian deposits provide rapid burial in fine-grained calcareous sediments. We studied 11 bone, 1 dentine and 14 enamel samples (these enamel samples were occasionally associated with traces of dentine (enamel + dentine))

analysed specimens. Elevation is referred to the local datum. **c**, Isolated left lower molar (m1 or m2) of *Stephanorhinus* ex gr. *etruscus/hundsheimensis*, from Dmanisi (labial view). Scale bar, 1 cm.

from 23 specimens of large mammals from multiple excavation units within stratum B1 (Fig. 1b, Extended Data Fig. 1, Extended Data Table 1, Supplementary Table 3). This is an ashfall deposit that contains faunal remains in a range of geomorphic contexts that are firmly dated to between 1.85 and 1.76 Myr ago¹⁹. High-resolution tandem mass spectrometry was used to confidently sequence ancient proteins from the set of faunal remains, after proteolytic digestion-based (protocols A and B) or digestion-free (protocol C) preparation of samples (for details of protocols, see Methods, Supplementary Information). Analysis of ancient DNA was attempted, unsuccessfully, on a subset of five bone and dentine specimens (Methods).

We recovered endogenous proteins from 15 out of the 23 specimens that we studied. Digestion-based peptide extraction from bone, dentine and enamel + dentine specimens led to the sporadic recovery (6 out of 19) of a limited number of collagen fragments. By contrast, digestion-free peptide extraction of enamel + dentine and bone specimens resulted in high rates of recovery of the enamel proteome (13 out of 14 specimens) (Extended Data Table 1).

The small proteome^{20,21} of mature dental enamel consists of structural proteins (amelogenin (multiple species express the X isoform, AMELX; and males also express the Y isoform, AMELY), enamelin (ENAM), amelotin (AMTN) and ameloblastin (AMBN)) as well as enamel-specific proteases that are secreted during amelogenesis (matrix metalloproteinase-20 (MMP20) and kallikrein 4 (KLK4)). The presence of non-specific proteins—such as serum albumin (ALB)—has also previously been reported in mature dental enamel²⁰ (Extended Data Table 2). The depth of coverage for these proteins varied considerably across their sequence, with some regions covered by over 1,000 peptide–spectrum matches (Extended Data Fig. 2). The high depth of coverage also enabled us to identify multiple isoforms of AMELX (Extended Data Fig. 3).

Multiple lines of evidence support the authenticity and the endogenous origin of the sequences that we recovered. Dental enamel proteins are extremely tissue-specific, and are confined to this mineral matrix²⁰. The amino acid composition of the intra-crystalline protein fraction (measured by amino acid racemization analysis) indicates that the dental enamel behaves as a closed system, and is unaffected by exchanges of amino acids and protein residues with the burial environment (Extended Data Fig. 4). The measured rate of asparagine and glutamine deamidation, which is a spontaneous form of hydrolytic damage that is consistently observed in ancient samples²², is particularly advanced. Deamidation in enamel from Dmanisi is higher than in the control sample of enamel, which provides support for the antiquity of the peptides that we recovered (Fig. 2a, Supplementary Information).

Other forms of non-enzymatic modifications are abundantly present as well. Tyrosine (Y) experienced mono- and di-oxidation, and tryptophan (W) was extensively converted into multiple oxidation products (Fig. 2b, Supplementary Information). The oxidative degradation of histidine (H) and conversion of arginine (R), leading to the accumulation of ornithine, were also observed (Supplementary Information). These modifications are absent or much less frequent in the control sample. Similarly, unlike in the control sample, the distribution of peptide lengths in the Dmanisi dataset is dominated by shorter fragments that are generated by advanced, diagenetically induced terminal hydrolysis²³ (Fig. 2c, d). Together, these independent lines of evidence clearly define the substantial biomolecular damage that has affected the enamel proteomes that we retrieved and independently support the authenticity of the amino acid sequences that we reconstructed. To demonstrate beyond reasonable doubt the correct peptide sequence assignments of our tandem mass spectra, we performed manual validation of peptide–spectrum matches, conducted fragment-ion intensity predictions and generated synthetic peptides for a range of phylogenetically informative and phosphorylated peptides (Methods, Supplementary Data).

We confidently detected site-specific phosphorylation (Fig. 3, Extended Data Figs. 2, 5), a physiological post-translational modification that is highly stable and tightly regulated in vivo and that has previously been detected in dental enamel proteins^{24,25}. Most of the phosphorylated sites that we identified belong to the S-X-E or S-X-phosphorylated S motifs, which are recognized by the secreted kinases of the FAM20C family; these kinases are involved in the phosphorylation of extracellular proteins and regulation of biomineralization²⁶. Spectra that supported the identification of serine phosphorylation were validated manually and by comparison with tandem mass spectra recorded from synthetic peptides (Supplementary Information), which confirmed the automated identifications from MaxQuant software. Phosphorylated serine and threonine residues may be subjected to spontaneous dephosphorylation. However, by complexing with the Ca²⁺ ions in the enamel hydroxyapatite matrix, the peptide-bound phosphate groups can remain stable over millennia, as recently observed for ancient bone²⁷. Previous studies have demonstrated that when complexed with the mineral matrix, approximately 3.8-Myr-old protein remains can be retrieved from sub-tropical environments¹³. The limited availability of free water in the enamel matrix further reduces spontaneous dephosphorylation via β -elimination. These observations demonstrate that the heavily modified proteome of the dental enamel retrieved from the approximately 1.77-Myr-old faunal material from Dmanisi is endogenous and almost complete.

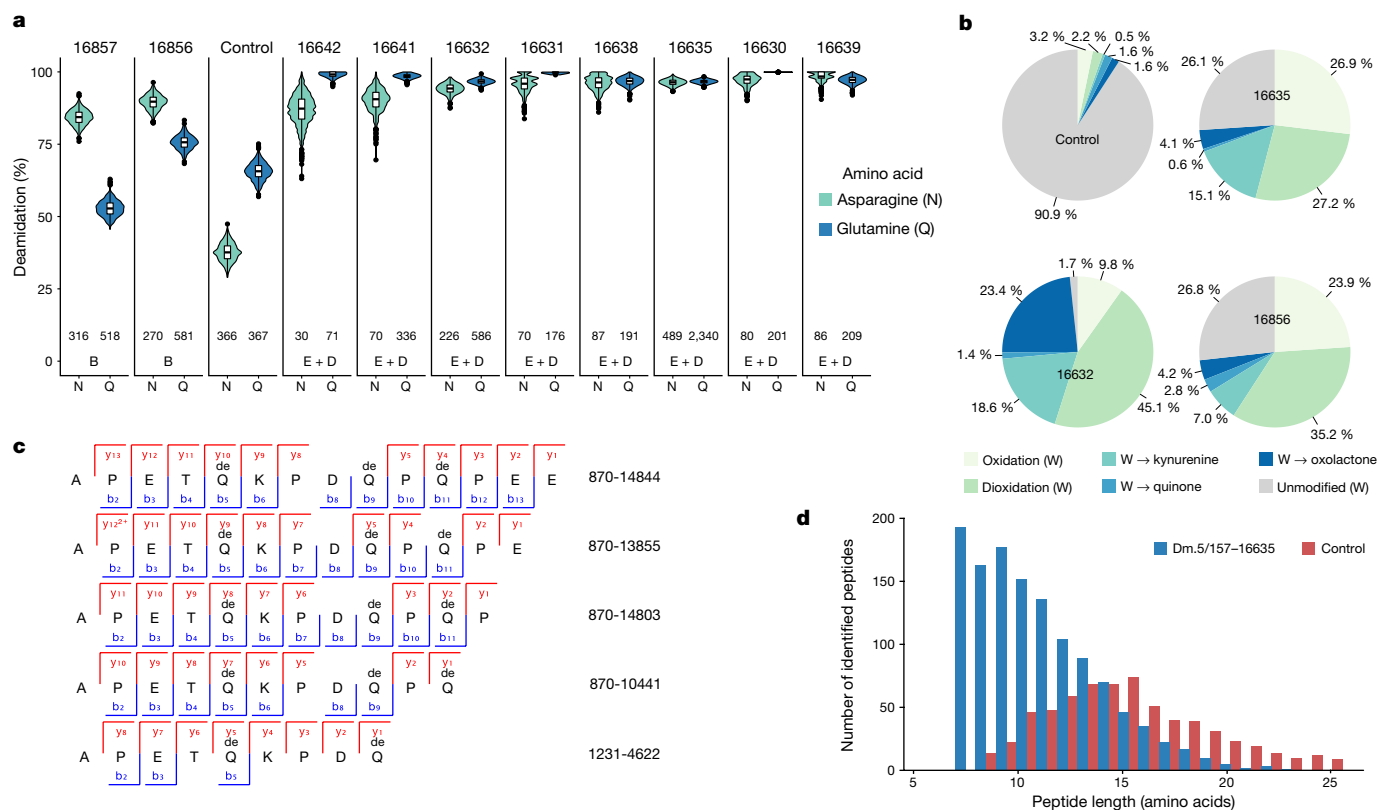

Fig. 2 | Degradation of the enamel proteome. **a**, Deamidation of asparagine (N) and glutamine (Q). Violin plots are based on 1,000 bootstrap replicates. The box plots define the range of the data, with whiskers extending to $1.5 \times$ the interquartile range, boxes showing the 25th to 75th percentiles and dots indicate the median. The tissue source is indicated: B, bone; D, dentine; and E, enamel. The number of peptides used for the calculation are shown at the bottom of the plots. Numbers above the plots refer to the CGG reference numbers for the specimens. **b**, Extent of tryptophan (W) oxidation leading to several diagenetic

products, measured as relative spectral counts. **c**, Alignment of deamidated (de) peptides (positions 124–137, ENAM) retrieved by digestion-free acid demineralization from specimen Dm.5/157–16635. Numbers to the right refer to stage-tip (see Supplementary Table 3 in the Supplementary Information) and MS/MS scan (see ‘Data availability’ in Methods) numbers. **d**, Bar plot of distribution of peptide lengths in undigested proteomes from the dental enamel of specimen Dm.5/157–16635 and of a control (mediaeval sheep or goat).

We used the proteome-sequence information that we recovered to improve taxonomic assignment and achieve sex attribution for some of the faunal remains from Dmanisi. Phylogenetic analysis of the five largest enamel + dentine proteomes, and of a moderately large bone proteome, enabled us to confirm or improve the morphological identification of their specimens of origin (Extended Data Fig. 6, Supplementary Figs. 10–15). Our confident identification of peptides specific for isoform Y of amelogenin (AMELY), which is encoded on the non-recombinant portion of the Y chromosome, indicates that four tooth specimens—Dm.6/151.4.A4.12–16630 (*Pseudodama*) (Dm. code refers to the accession number in the Georgian National Museum (GNM) and the appended five-digit number refers to the reference code of the sample from the Centre for GeoGenetics (CGG)), Dm.69/64.3.B1.53–16631 (Cervidae), Dm.8/154.4.A4.22–16639 (Bovidae) and Dm.M6/7.II.296–16856 (Cervidae)—belonged to male individuals²¹ (Extended Data Fig. 7a–d).

An enamel + dentine fragment from specimen Dm.5/157–16635, a lower molar assigned to a *Stephanorhinus* of the group that includes *Stephanorhinus etruscus* and *Stephanorhinus hundsheimensis* (*Stephanorhinus* ex gr. *etruscus/hundsheimensis*) (Fig. 1c, Supplementary Information), returned the highest proteome-sequence coverage, which encompassed a total of 875 amino acids across 987 peptides (6 proteins) (Extended Data Fig. 2, Supplementary Information). Following the alignment of the enamel protein sequences retrieved from Dm.5/157–16635 against their homologues from all extant rhinoceros species plus the extinct woolly rhinoceros (*C. antiquitatis*) and Merck’s rhinoceros (*S. kirchbergensis*), phylogenetic reconstructions place the Dmanisi specimen closer to

these two extinct rhinoceroses than to the extant Sumatran rhinoceros (*Dicerorhinus sumatrensis*), as an early divergent sister lineage (Fig. 4, Extended Data Fig. 8).

Our phylogenetic reconstruction confidently recovered the expected differentiation of the *Rhinoceros* genus from other genera that we considered, and is consistent with previous cladistic²⁸ and genetic analyses²⁹ (Supplementary Information). This topology defines two-horned

Fig. 3 | Sequence motif analysis of phosphorylation sites in the proteome of ancient enamel. The over-representation of specific amino acids within six positions of the N and C termini of the phosphorylated amino acid (position 0) is indicated. Extended Data Figure 5 provides tandem mass spectra examples of both S-X-E and S-X-phosphorylated S motifs.

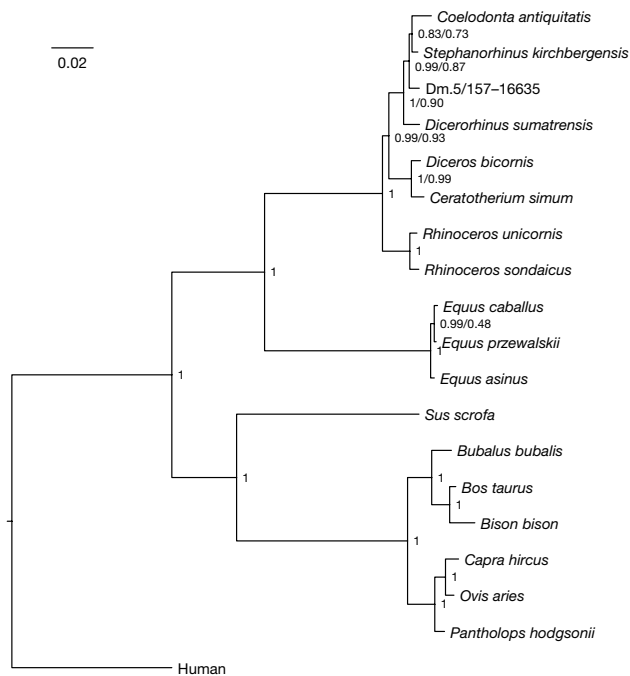

Fig. 4 | Phylogenetic relationships between the comparative dataset of enamel proteomes and specimen Dm.5/157–16635. Consensus tree from Bayesian inference on the concatenated alignment of six enamel proteins, using *Homo sapiens* as an outgroup. For each bipartition, we show the posterior probability obtained from the Bayesian inference. For bipartitions for which the Bayesian and the maximum-likelihood inference support differs, we show the support obtained using the latter on the right. Scale indicates the estimated branch lengths.

rhinoceroses as monophyletic and the one-horned condition as plesiomorphic, as previously proposed (Supplementary Information). We caution, however, that the higher-level relationships that we observe between the rhinoceros monophyletic clades might be affected by demographic events such as incomplete lineage sorting³⁰ and/or gene flow between groups³¹, owing to the limited number of markers that we considered. A confident and stable reconstruction of the structure of the Rhinocerotidae family needs the strong support that only high-resolution whole-genome sequencing can provide. Regardless, the highly supported placement of the Dmanisi rhinoceros in the clade formed by *Stephanorhinus*, the woolly rhinoceros and the Sumatran rhinoceros will remain unaffected, should the deeper phylogenetic relationships between the *Rhinoceros* genus and other family members be revised (Extended Data Fig. 8).

The phylogenetic relationships of the genus *Stephanorhinus* within the family Rhinocerotidae—as well as those of the several species recognized within this genus—are contentious. *Stephanorhinus* was initially included in the extant southeast-Asian genus *Dicerorhinus*, which is represented by *D. sumatrensis*³². This hypothesis has been rejected, and *Stephanorhinus* has been identified on the basis of morphological data as a sister taxon of the woolly rhinoceros³³. Furthermore, analysis of ancient DNA supports a sister relationship between the woolly rhinoceros and *D. sumatrensis*^{7,34,35}.

As the *Stephanorhinus* ex gr. *etruscus/hundsheimensis* sequences from Dmanisi branch off basal to the common ancestor of the woolly rhinoceros and Merck's rhinoceros, these two species most probably derived from an early *Stephanorhinus* lineage that expanded eastward from western Eurasia. Throughout the Pliocene and Pleistocene epochs, *Coelodonta* adapted to continental and, later, to cold-climate habitats in central Asia. The earliest representative of this genus, *Coelodonta thibetana*, displayed some clear *Stephanorhinus*-like anatomical features³³. The genus *Stephanorhinus* was present in eastern Europe and Anatolia³⁵ at least since the late Miocene epoch, and the Dmanisi

specimen most probably represents an Early Pleistocene descendent of the western-Eurasian branch of this genus.

Our phylogenetic reconstructions show that, as currently defined, the genus *Stephanorhinus* is paraphyletic, which is consistent with previous morphological and palaeo-biogeographical evidence (Supplementary Information). Accordingly, a systematic revision of the genera *Stephanorhinus* and *Coelodonta*, as well as their closest relatives, is needed.

In this study, we show that the mass spectrometric sequencing of the enamel proteome can overcome the time limitations of the preservation of ancient DNA, as well as the reduced phylogenetic content of COL1 sequences. Given the abundance of teeth in the palaeontological record, the approach presented here holds the potential to address a wide range of questions that pertain to the Early and Middle Pleistocene evolutionary history of a large number of mammals (including hominins), at least in temperate climates.

METHODS

Dmanisi and sample selection. Dmanisi is located about 65 km southwest of Tbilisi, in the Kvemo Kartli region of Georgia, at an elevation of 910 m above sea level (41° 20' N, 44° 20' E)^{10,18}. The 23 fossil specimens that we analysed were retrieved from stratum B1, in excavation blocks M17, M6, block 2 and area R11 (Extended Data Fig. 1, Extended Data Table 1). Stratum B deposits date to between 1.78 and 1.76 Myr ago¹⁹. All of the specimens that we analysed were collected between 1984 and 2014, and their taxonomic identification was based on traditional comparative anatomy.

After the sample preparation and data acquisition for the Dmanisi specimens was concluded, we applied the whole experimental procedure to a mediaeval-period enamel + dentine specimen from a sheep or goat (ovicaprine); this was used as control. For this sample, we used extraction protocol C (see 'Extraction protocol C (digestion-free acid demineralization)') and generated tandem mass spectrometry data using a Q Exactive HF mass spectrometer (Thermo Fisher Scientific). The data were searched against the goat proteome, downloaded from the NCBI Reference Sequence Database (RefSeq) archive on 31 May 2017 (Supplementary Information). The ovicaprine specimen was found at the 'Hotel Skandinavia' site (Århus) and stored at the Natural History Museum of Denmark (Copenhagen).

Biomolecular preservation. We assessed the potential for preservation of ancient proteins before proteomic analysis by measuring the extent of amino acid racemization in a subset of samples (6 out of 23)³⁶. Enamel chips with all dentine removed were powdered, and two subsamples per specimen were subjected to analysis of their free and total hydrolysable amino acid fractions. Samples were analysed in duplicate by reverse-phase high-performance liquid chromatography, with standards and blanks run alongside each of them (Supplementary Information). The values of the D over L ratios of aspartic acid plus asparagine, glutamic acid plus glutamine, phenylalanine and alanine were assessed (Extended Data Fig. 4) to provide an overall estimate of intra-crystalline protein decomposition.

Proteomics. All of the sample preparation procedures for mass spectrometric analysis of ancient proteins were conducted in laboratories dedicated to the analysis of ancient DNA and ancient proteins, in clean rooms fitted with filtered ventilation and positive pressure (consistent with recent recommendations for ancient protein analysis³⁷). A mock 'extraction blank', containing no starting material, was prepared, processed and analysed together with each batch of ancient samples.

Sample preparation. The external surface of bone samples was gently removed, and the remaining material was subsequently powdered. Enamel fragments, occasionally mixed with small amounts of dentine, were removed from teeth with a cutting disc and subsequently crushed into a rough powder. Unless otherwise specified, ancient protein residues were extracted from approximately 180–220 mg of mineralized material using three different extraction protocols: protocols A, B and C (see below and Supplementary Information for more detailed descriptions of protocols). **Extraction protocol A (filter-aided sample preparation).** Tryptic peptides were generated using a filter-aided sample preparation approach³⁸, as previously performed on ancient samples³⁹.

Extraction protocol B (GuHCl solution and digestion). Bone or enamel + dentine powder was demineralized in 1 ml 0.5 M EDTA pH 8.0. After removal of the supernatant, all demineralized pellets were resuspended in a 300 µl solution containing 2 M guanidine hydrochloride (GuHCl, Thermo Scientific), 100 mM Tris pH 8.0, 20 mM 2-chloroacetamide (CAA), 10 mM Tris (2-carboxyethyl)phosphine (TCEP) in ultrapure water^{40,41}. A total of 0.2 µg of mass-spectrometry-grade rLysC (Promega P/N V1671) enzyme was added before the samples were incubated for 3–4 h at 37 °C with agitation. Samples and negative controls were subsequently diluted to 0.6 M GuHCl, and 0.8 µg of mass-spectrometry-grade trypsin (Promega P/N V5111) was added. Next, samples and negative controls were incubated overnight under mechanical agitation at 37 °C. On the following day, samples were acidified, and the tryptic peptides were purified on C18 stage-tips, as previously described⁴².

Extraction protocol C (digestion-free acid demineralization). Dental enamel powder, with possible trace amounts of dentine, was demineralized in 1.2 M HCl at room temperature, after which the solubilized protein residues were directly cleaned and concentrated on stage-tips (Supplementary Information, section 5.1). The sample prepared on stage-tip no. 1217 was processed with 10% trifluoroacetic acid (TFA) instead of 1.2 M HCl. All other parameters and procedures were identical to those used for all other samples extracted with protocol C.

Tandem mass spectrometry. Different sets of samples (Supplementary Information, sections 5.1, 5.2) were analysed by nanoflow liquid chromatography coupled to tandem mass spectrometry (MS/MS) on an EASY-nLC 1000 or 1200 system connected to a Q-Exactive, a Q-Exactive Plus or a Q-Exactive HF (Thermo Scientific) mass spectrometer. Before and after each MS/MS run measuring ancient or extraction blank samples, two successive MS/MS runs were included in the sample queue to prevent carryover contamination between the samples. These consisted of an MS/MS run with an injection exclusively of the buffer used to resuspend the samples (0.1% TFA and 5% acetonitrile) ('MS/MS blank'), followed by a second MS/MS run with no injection ('MS/MS wash').

Data analysis. Raw data files generated during MS/MS spectral acquisition were searched using MaxQuant⁴³ version 1.5.3.30 and PEAKS⁴⁴ version 7.5. A two-stage peptide–spectrum matching approach was adopted (Supplementary Information, section 5.3). Raw files were initially searched against a target and reversed database of collagen and enamel proteins retrieved from the UniProt and RefSeq archives^{45,46}, taxonomically restricted to mammalian species. A database of partial COL1A1 and COL1A2 sequences from cervid species⁴⁷ was also included. The results from the preliminary analysis were used for a first provisional reconstruction of protein sequences (MaxQuant search 1, MQ1).

For specimens with a dataset that resulted in a narrower—although not fully resolved—initial taxonomic placement, a second MaxQuant search (MQ2) was performed using a new protein database taxonomically restricted to the 'order' taxonomic rank, as determined after MQ1. For the MQ2 matching of the MS/MS spectra from specimen Dm.5/157–16635, partial sequences of serum albumin and enamel proteins from Sumatran rhinoceros (*D. sumatrensis*), Javan rhinoceros (*Rhinoceros sondaicus*), Indian rhinoceros (*Rhinoceros unicornis*), woolly rhinoceros (*C. antiqutatis*), Merck's rhinoceros (*S. kirchbergensis*) and black rhinoceros (*Diceros bicornis*) were also added to the protein database. All of the protein sequences from these species were reconstructed from draft genomes for each species (Supplementary Information, L. Dalen and M. T. P. Gilbert, unpublished data).

For each MaxQuant and PEAKS search, enzymatic digestion was set to 'unspecific' and the following variable modifications were included: oxidation (for M), deamidation (for N and Q), N-terminal pyro-Glu (for Q), N-terminal pyro-Glu (for E), hydroxylation (for P) and phosphorylation (for S). The error tolerance was set to 5 ppm for the precursor and to 20 ppm (or 0.05 Da) for the fragment ions in MaxQuant and PEAKS, respectively. For searches of data generated from sample fractions partially or exclusively digested with trypsin, another MaxQuant and PEAKS search was conducted using the 'enzyme' parameter set to 'Trypsin/P'. Carbamidomethylation (for C) was set: (i) as a fixed modification, for searches of data generated from sets of sample fractions exclusively digested with trypsin or (ii) as a variable modification, for searches of data generated from sets of sample fractions partially digested with trypsin. For searches of data generated exclusively from undigested sample fractions, carbamidomethylation was not included as a modification.

The datasets that were re-analysed with MQ2 search were also processed with the PEAKS software using the entire workflow (PEAKS de novo to PEAKS SPIDER) to detect hitherto unreported single-amino-acid polymorphisms. Any amino acid substitution detected by the SPIDER homology search algorithm was validated by repeating the MaxQuant search (MQ3). In MQ3, the protein database used for MQ2 was modified to include the amino acid substitutions detected by the SPIDER algorithm.

Reconstruction of ancient protein sequences. The peptide sequences confidently identified by the MQ1, MQ2 and MQ3 were aligned using the software Geneious⁴⁸ (v.5.4.4, substitution matrix BLOSUM62). The peptide sequences confidently identified by the PEAKS searches were aligned using an in-house-generated R-script. A consensus sequence for each protein from each specimen was generated in FASTA format, without filtering on depth of coverage. Amino acid positions that were not confidently reconstructed were replaced by an X. Newly identified single-amino-acid polymorphisms discovered through PEAKS were only accepted if these were further validated by repeating the MaxQuant search (MQ3). All isoleucines were converted into leucines, as standard MS/MS cannot differentiate between these two isobaric amino acids. For possible deamidated sites, we checked whether there were positions in our reference sequence database at which both Q and E or both N and D occurred in the same position, and for which we also had ancient sequences matching. For specimen Dm.5/157–16635, only one such position existed, and this was replaced by an X in our consensus sequence. Based on parsimony, for other Q, E, N and D positions we called the amino acid present in the reference proteome, regardless of the phylogenetic relevance. The output of MQ2 and MQ3 was used to extend the coverage of the ancient protein sequences initially identified in MQ1. For specimen DM.5/157–16335, all of the experimentally identified peptides—as well as the respective best-matching MS/MS spectra covering the sites informative for Rhinocerotidae phylogenetic inference—are provided as Supplementary Data. All of the reported MS/MS spectra are annotated using the advanced annotation mode of MaxQuant. Selected spectra matching peptides that cover phylogenetically informative amino acid positions were manually inspected, validated and annotated by an experienced mass spectrometrists, in all cases in full agreement with bioinformatic sequence assignment (Supplementary Data). We used MS²PIP fragment-ion spectral-intensity prediction⁴⁹ (version v.20190312, model version 20190107 HCD) to demonstrate that the experimentally observed fragment-ion intensities are highly correlated with the theoretical ones (Supplementary Fig. 3). Finally, we generated synthetic peptides for 19 selected peptides covering Rhinocerotidae single-amino-acid polymorphisms in DM.5/157–16635.

Post-translational modifications. **Deamidation.** After removal of likely contaminants, the extent of glutamine and asparagine deamidation was estimated for

individual specimens using the MaxQuant output files, as previously published⁴¹ (Supplementary Information).

Other spontaneous chemical modifications. Spontaneous post-translational modifications (PTMs) associated with chemical protein damage were searched using the PEAKS PTM tool and the dependent-peptides search mode⁵⁰ in MaxQuant. In the PEAKS PTM search, all modifications in the Unimod database were considered. The mass error was set to 5.0 ppm and 0.5 Da for precursor and fragment, respectively. For PEAKS, the de novo average-local-confidence (ALC) score was set to a threshold of 15% and the peptide hit threshold was set to 30. The results were filtered with a false discovery rate of 5%, de novo ALC score of 50% and a protein hit threshold of ≥ 20 . The MaxQuant dependent-peptide search was carried out with the same search settings as described in 'Data analysis' and with a dependent-peptide false discovery rate of 1% and a mass bin size of 0.0065 Da.

Phosphorylation. Class I phosphorylation sites were selected with localization probabilities of ≥ 0.98 in the Phospho(ST)Sites MaxQuant output file. Sequence windows of ± 6 amino acids from all identified sites were compared against a background file containing all unphosphorylated peptides, using a linear kinase sequence motif enrichment analysis in IceLogo (version 1.3.8)⁵¹.

Phylogenetic analysis. Reference datasets. We assembled a reference dataset that consisted of publicly available protein sequences from representative ungulate species belonging to the following families: Equidae, Rhinocerotidae, Suidae and Bovidae (Supplementary Information, sections 7, 8). As Cervidae and carnivores are absent from protein sequence databases to varying extents, we did not attempt phylogenetic placement of samples from these taxa. Instead, we conducted our phylogenetic analysis on the five best-performing enamel proteomes (Dm.5/154.2.A4.38–16632, Dm.5/157–16635, Dm.5/154.1.B1.1–16638, Dm.8/154.4.A4.22–16639 and Dm.8/152.3.B1.2–16641) and the largest bone proteome (Dm.bXI.North.B1a.collection–16658) that we recovered (Extended Data Table 2).

We extended this dataset with the protein sequences from extinct and extant rhinoceros species, including woolly rhinoceros (*C. antiquitatis*), Merck's rhinoceros (*S. kirchbergensis*), Sumatran rhinoceros (*D. sumatrensis*), Javan rhinoceros (*R. sondaicus*), Indian rhinoceros (*R. unicornis*) and black rhinoceros (*D. bicornis*). Their corresponding protein sequences were obtained following translation of high-throughput DNA sequencing data, after filtering reads with mapping quality lower than 30 and nucleotides with base quality lower than 20, and calling the majority rule consensus sequence using ANGSD⁵². For the woolly rhinoceros and Merck's rhinoceros, we excluded the first and last five nucleotides of each DNA fragment to minimize the effect of post-mortem damage to the ancient DNA⁵³. Each consensus sequence was formatted as a separate blast nucleotide database. We then performed a blastn⁵⁴ alignment using the corresponding white rhinoceros sequence as a query, favouring ungapped alignments to recover translated and spliced protein sequences. The resulting alignments were processed using ProSplign algorithm from the NCBI Eukaryotic Genome Annotation Pipeline⁵⁵ to recover the spliced alignments and translated protein sequences.

Construction of phylogenetic trees. For each specimen, multiple sequence alignments for each protein were built using MAFFT⁵⁶ and concatenated onto a single alignment per specimen. These were inspected visually to correct obvious alignment mistakes, and all of the isoleucine residues were substituted with leucine ones to account for indistinguishable isobaric amino acids at the positions at which the ancient protein carried one of these amino acids. On the basis of these alignments, we inferred the phylogenetic relationship between the ancient samples and the species included in the reference dataset using three approaches: distance-based neighbour joining, maximum-likelihood and Bayesian phylogenetic inference (Supplementary Information).

Neighbour-joining trees were built using the phangorn⁵⁷ R package, restricting to sites covered in the ancient samples. Genetic distances were estimated using the JTT model, considering pairwise deletions. We estimated bipartition support through a non-parametric bootstrap procedure using 500 pseudoreplicates. We used PHyML 3.1⁵⁸ for maximum-likelihood inference on the basis of the whole concatenated alignment. For likelihood computation, we used the JTT substitution model with two additional parameters for modelling rate heterogeneity and the proportion of invariant sites. Bipartition support was estimated using a non-parametric bootstrap procedure with 500 replicates. Bayesian phylogenetic inference was carried out using MrBayes 3.2.6⁵⁹ on each concatenated alignment, partitioned per gene. Although we chose the JTT substitution model in the two approaches above, we allowed the Markov chain to sample parameters for the substitution rates from a set of predetermined matrices, as well as the shape parameter of a gamma distribution for modelling across-site rate variation and the proportion of invariable sites. The Markov chain Monte Carlo algorithm was run with 4 chains for 5,000,000 cycles. Sampling was conducted every 500 cycles and the first 25% was discarded as burn-in. Convergence was assessed using Tracer v.1.6.0, which estimated an effective sample size greater than 5,500 for each individual, which indicates that there was reasonable convergence for all runs.

Analysis of ancient DNA. The samples were processed using strict ancient DNA guidelines in a clean laboratory facility at the Natural History Museum of Denmark (University of Copenhagen). DNA extraction was attempted on five of the ancient animal samples (Supplementary Information, sections 9, 13). Powdered samples (120–140 mg) were extracted using a silica-in-solution method^{12,60}. To prepare the samples for next-generation sequencing, 20 μ l of DNA extract was built into a blunt-end library using the NEBNext DNA Sample Prep Master Mix Set 2 (E6070) with Illumina-specific adapters. The libraries were PCR-amplified with inPE1.0 forward primers and custom-designed reverse primers with a six-nucleotide index⁶¹. Two extracts (MA399 and MA2481, from specimens D4–16859 and Dm.5/157–16635, respectively) yielded detectable DNA concentrations (Supplementary Table 9). The libraries generated from specimen 16859 and 16635 were processed on different flow cells. They were pooled with others for sequencing on an Illumina 2000 platform (MA399_L1 and MA399_L2) using 100-bp single-read chemistry, and on an Illumina 2500 platform (MA2481_L1) using 81-bp single-read chemistry.

The data were base-called using the Illumina software CASAVA 1.8.2 and sequences were demultiplexed with a requirement of a full match of the six nucleotide indexes that were used. Raw reads were processed using the PALEOMIX pipeline following published guidelines⁶², mapping against the cow nuclear genome (*Bos taurus* 4.6.1, accession GCA_000003205.4), the cow mitochondrial genome (*Bos taurus*), the red deer mitochondrial genome (*Cervus elaphus*, accession AB245427.2) and the human nuclear genome (GRCh37/hg19) using BWA back-track⁶³ v.0.5.10 with the seed disabled. All other parameters were set as default. PCR duplicates from mapped reads were removed using the picard tool MarkDuplicate (<http://picard.sourceforge.net/>).

Morphological measurements of specimen Dm.5/157–16635. We followed a previously published methodology³². The maximal length of the tooth was measured with a digital calliper at the lingual side of the tooth and parallel to the occlusal surface. All measurements are given in mm (Supplementary Information, section 3).

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this paper.

Data availability

All of the mass spectrometry proteomics data have been deposited in the ProteomeXchange Consortium (<http://proteomecentral.proteomexchange.org>) via the PRIDE partner repository with the dataset identifier PXD011008. Genomic BAM files used for Rhinocerotidae protein sequence translation and protein sequence alignments used for phylogenetic reconstruction are available on Figshare (<https://doi.org/10.6084/m9.figshare.7212746>).

Code availability

The in-house R script used to align the peptide sequences confidently identified by the PEAKS searches is available to everyone upon request to the corresponding authors.

Extended Data Fig. 1 | Generalized stratigraphic profiles for Dmanisi, indicating origins of the specimens. **a**, Type section of the Dmanisi M5 excavation block. **b**, Stratigraphic profile of excavation area M6. M6 preserves a larger gully associated with the pipe-gully phase of stratigraphic-geomorphic development in stratum B1. The thickness of the stratum B1 gully fill extends to the basalt surface but includes ‘rip-ups’ of strata A1 and A2, showing that the deposits in stratum B1 post-date those of stratum A. **c**, Stratigraphic section of excavation area M17. Here, Stratum B1 was deposited after the erosion of stratum A deposits.

The stratigraphic position of specimen Dm.5/157–16635 is highlighted with a red diamond. The Masavara basalt is about 50 cm below the base of the profile shown. **d**, Northern section of block 2. Following the collapse of a pipe and erosion to the basalt, the deeper part of this area was filled with local gully fill of strata B1x, B1y and B1z. Note the uniform burial of all stratum B1 deposits by strata B2, B3 and B4. The sampled specimens are indicated by the five-digit CGG numbers. Extended Data Table 1 provides both the CGG and GNM specimen numbers.

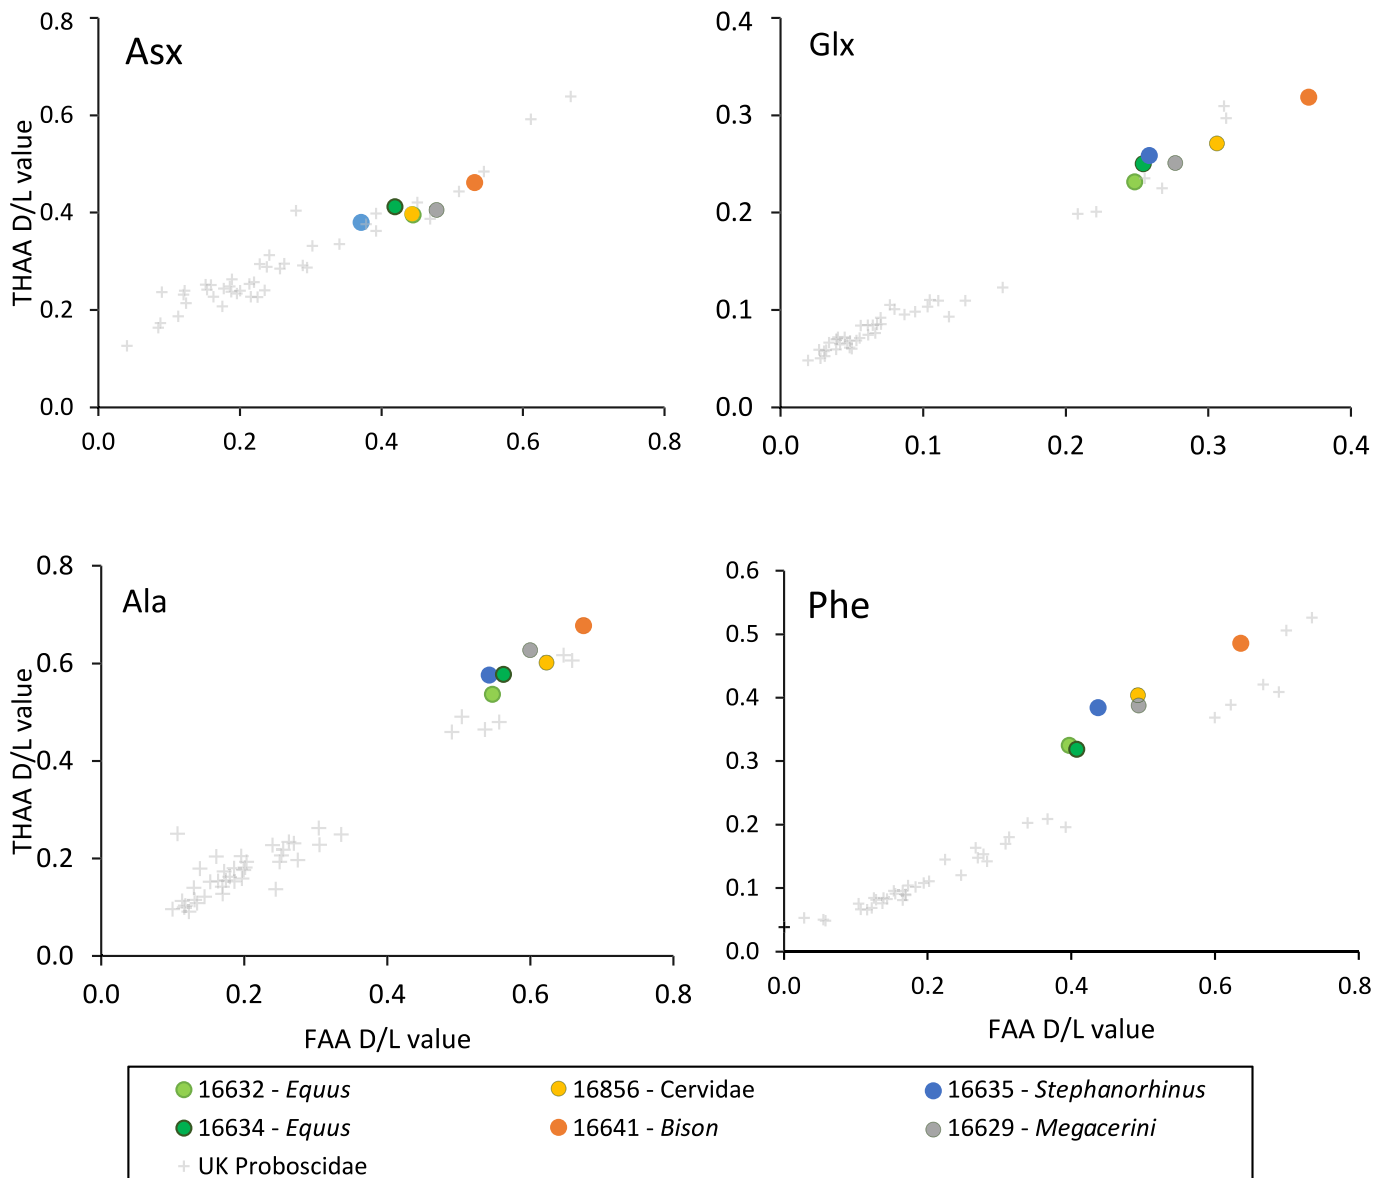

Extended Data Fig. 2 | Proteome-sequence coverage for specimen Dm.5/157-16635. a, c, e, g, i, j, Peptide-spectrum match (PSM) sequence coverage of the proteins AMBN (a), ENAM (c), AMELX (e), AMTN (g), MMP20 (i) and ALB (j). Annotations include ‘amino acid position, amino acid called in that position (number of PSMs and peptides covering that position)’ for the phylogenetically informative single-amino-acid polymorphisms within Rhinocerotidae. **b, d, f, h,** Frequency (per cent) of phosphorylated (green) and unphosphorylated (red) PSMs per amino acid position for AMBN (b), ENAM (d), AMELX (f) and AMTN (h). Numbers

within the bars provide the PSM counts. **k,** Violin plot of distribution of PSM coverage for all covered sites ($n = 693$), and for sites of phylogenetic relevance (single-amino-acid polymorphisms, $n = 30$). The box plots define the range of the data, with whiskers extending to $1.5\times$ interquartile range, boxes denoting the 25th and 75th percentiles and dots indicating the median. All panels are based only on MaxQuant search results. The Supplementary Data contains examples of MS/MS spectra, and fragment-ion series alignments for each of the marked single-amino-acid polymorphisms.

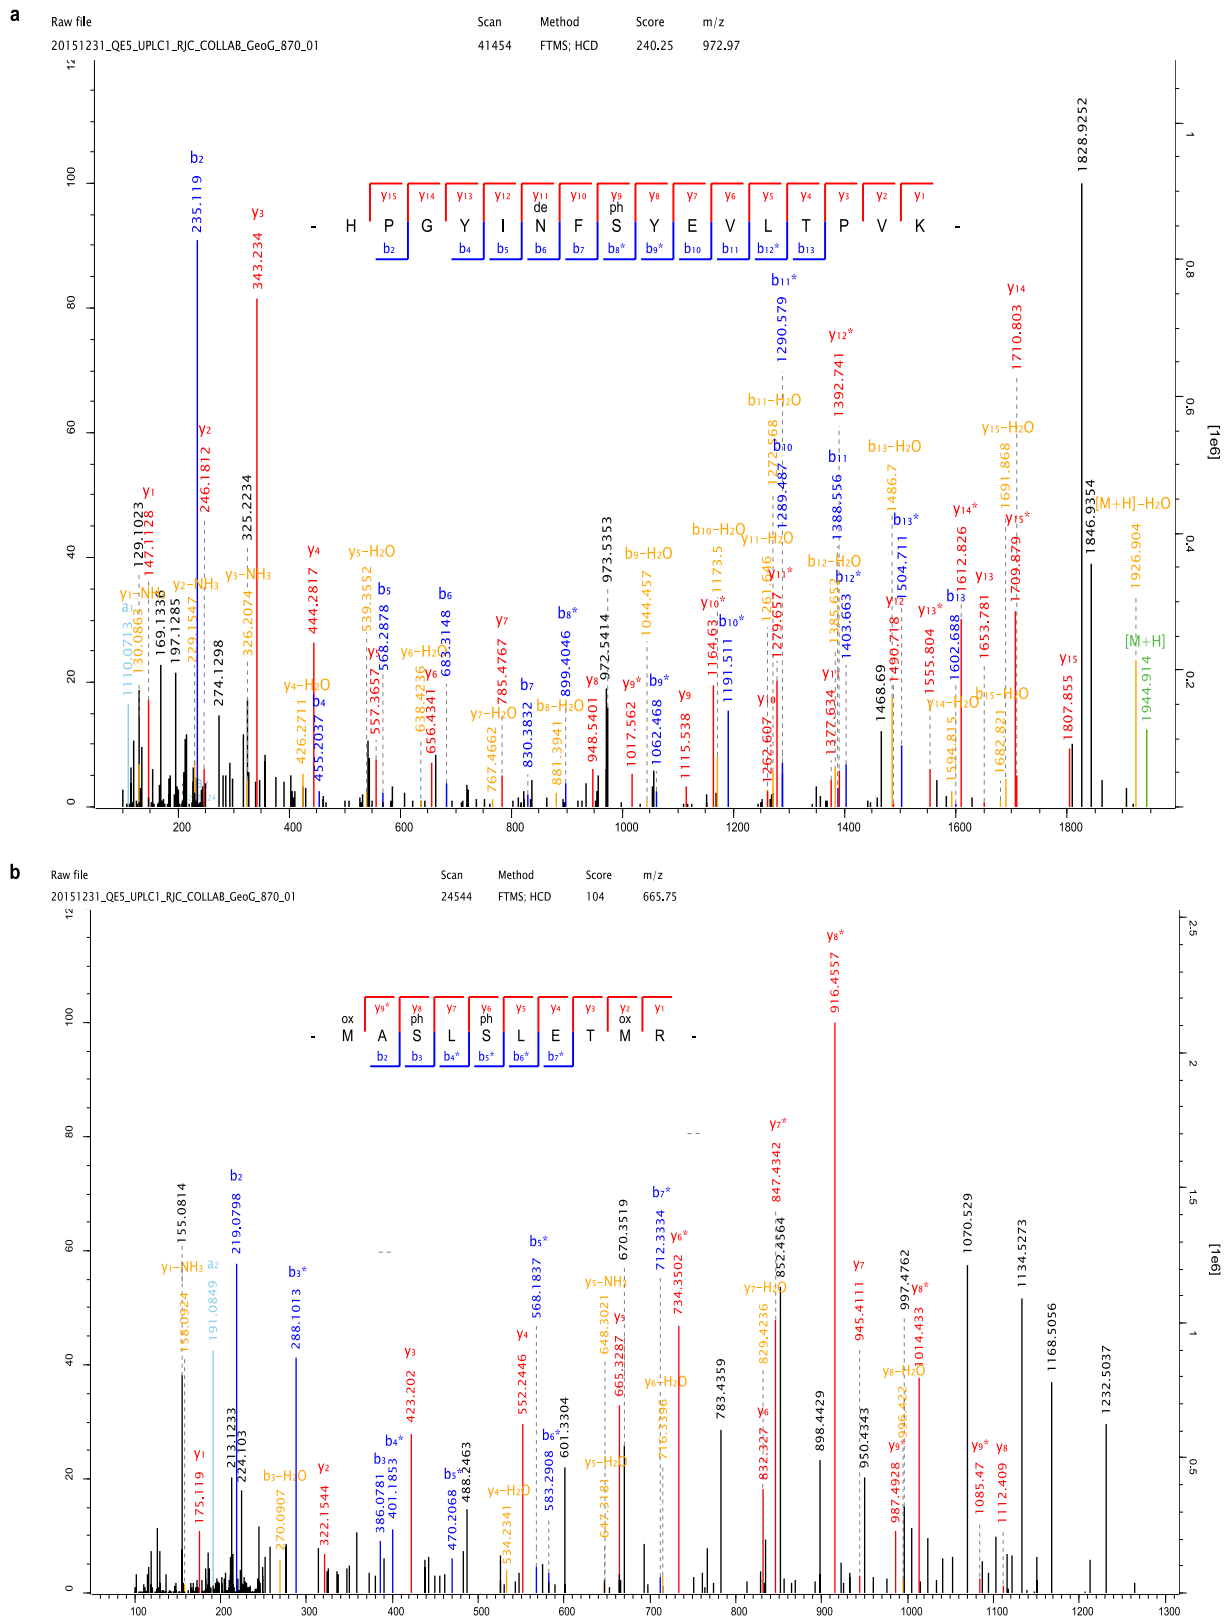

Extended Data Fig. 3 | Peptide and fragment-ion coverage of AMELX isoform 1 and isoform 2 from specimen Dm.M6/7.II.296–16856. Peptides specific to AMELX isoform 1 and isoform 2 appear in the top and bottom parts of the figure, respectively. No AMELX isoform 2 is currently reported in public databases for the Cervidae group. Accordingly, the

AMELX-isoform-2-specific peptides were identified by MaxQuant spectral matching against bovine (*Bos taurus*) AMELX isoform 2 (UniProt accession number P02817-2). AMELX isoform 2 (also known as leucine-rich amelogenin peptide (LRAP)) is a naturally occurring isoform of AMELX from the translation product of an alternatively spliced transcript.

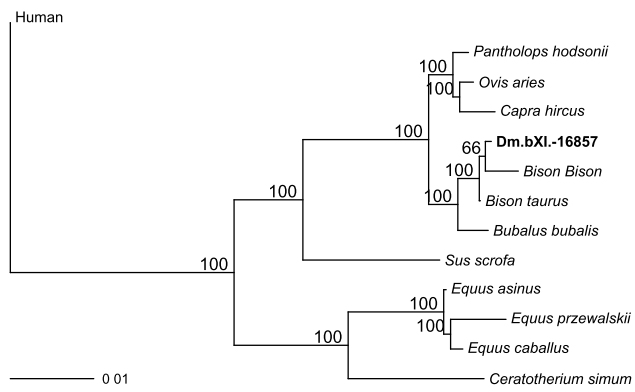

Extended Data Fig. 4 | Amino acid racemization. Extent of intra-crystalline racemization in enamel for the free amino acid (FAA, x axis) fraction and the total hydrolysable amino acids (THAA, y axis) fraction for four amino acids (Asp plus Asn (here denoted Asx), Glu plus Gln (here denoted Glx), Ala and Phe). Note the differences in axis scale.

Intra-crystalline data from Proboscidea enamel from a range of sites in the UK⁶⁴ have been shown for comparison (grey crosses). Taxa from both Dmanisi and the UK exhibit a similar relationship between FAA and THAA racemization, and R^2 values have been calculated on the basis of a polynomial relationship (order = 2, all > 0.93).

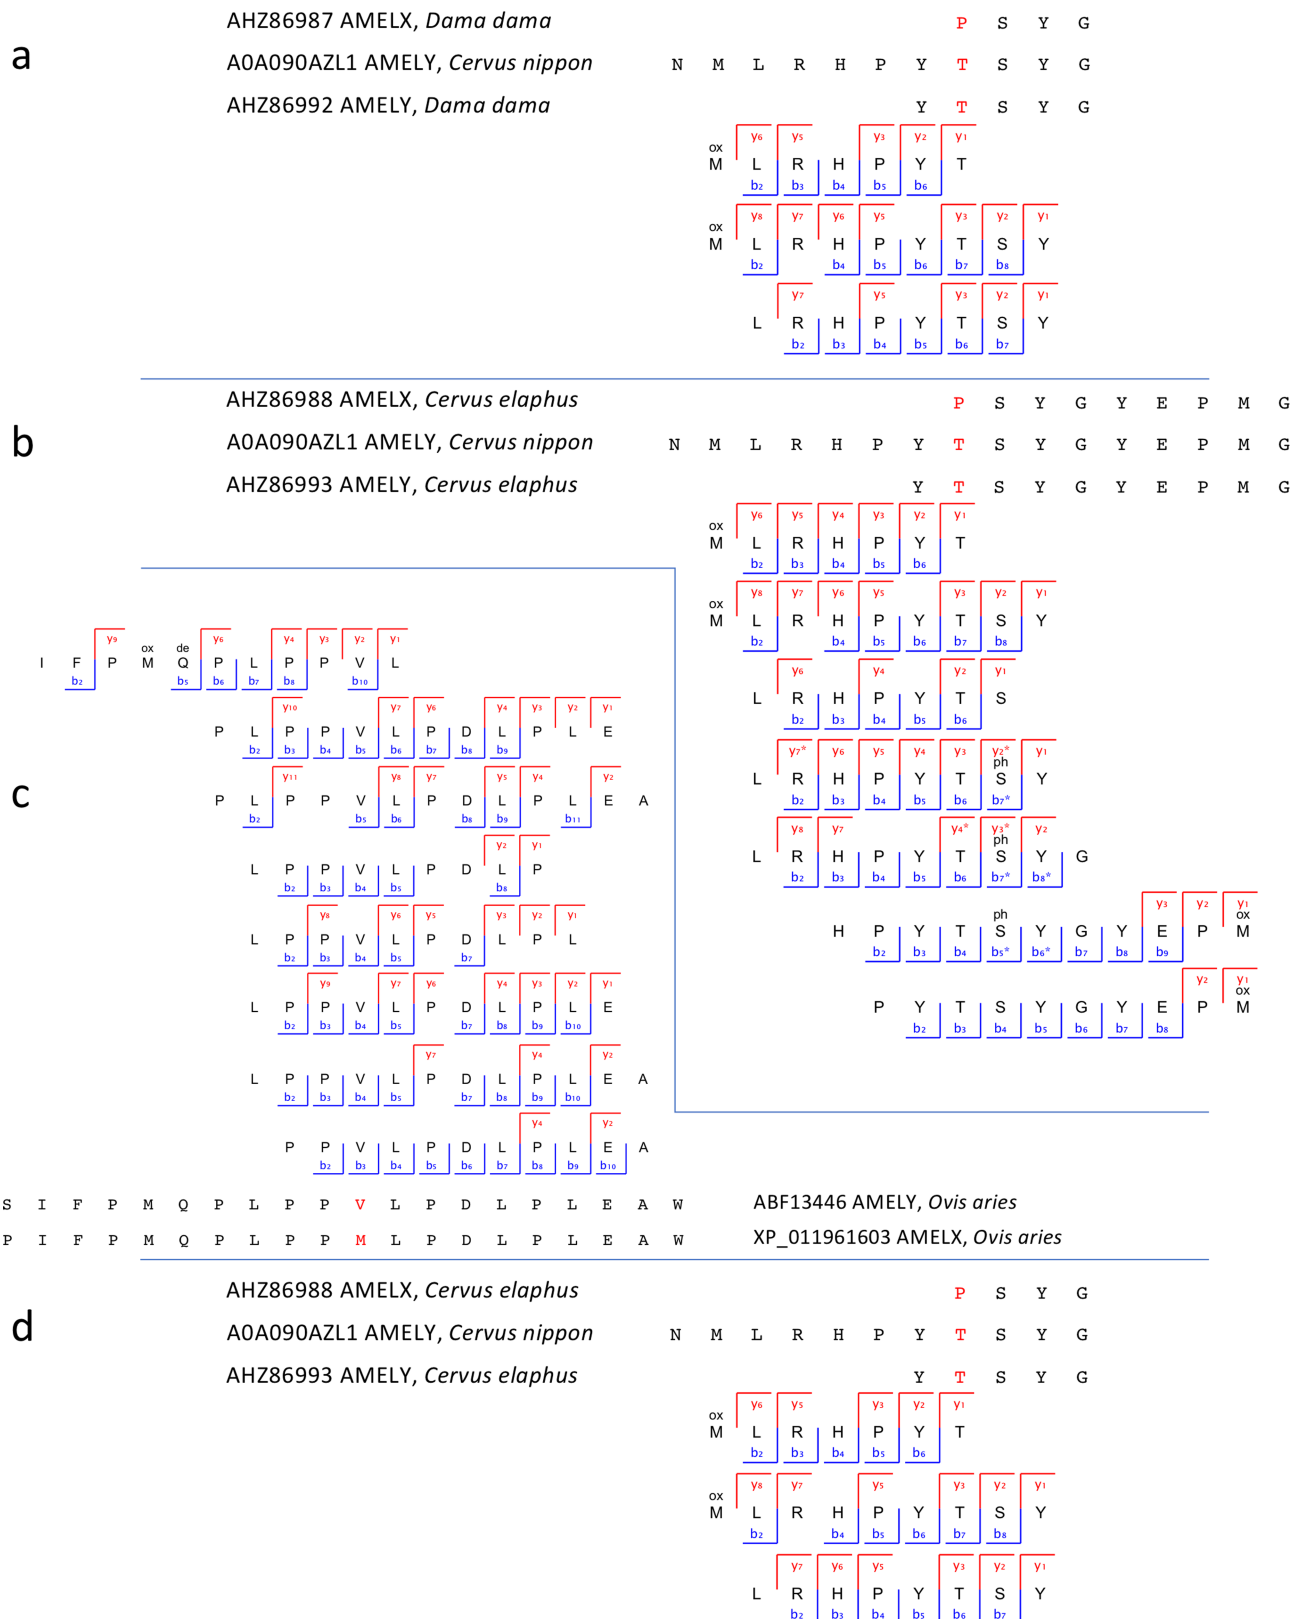

Extended Data Fig. 5 | Phosphorylation in the proteome of ancient enamel. Annotated spectra including phosphorylated (here denoted ph) serine (S). **a**, Phosphorylation in the S-X-E motif of AMELX. **b**, Phosphorylation in the S-X-phosphorylated S motif of AMBN.

Phosphorylation was independently observed in all three separate analyses of Dm.5/157–16635, including multiple spectra and peptides (Extended Data Fig. 2).

Extended Data Fig. 6 | Phylogenetic relationships between the comparative reference dataset and specimen Dm.bXI-16857. Consensus tree from Bayesian inference. The posterior probability of each bipartition is shown as a percentage to the left of each node.

Extended Data Fig. 7 | AMELY-specific matches. a, Specimen Dm.6/151.4.A4.12–16630. b, Specimen Dm.69/64.3.B1.53–16631. c, Specimen Dm.8/154.4.A4.22–16639. d, Specimen Dm.M6/7.II.296–

Extended Data Fig. 8 | Effect of the missingness in the tree topology. **a**, Maximum-likelihood phylogeny obtained using PhyML and the protein alignment that excludes Dm.5/157–16635. **b**, Topologies obtained from 100 random replicates of the woolly rhinoceros (*C. antiquitatis*). In each replicate, the number of missing sites was similar to that observed for

the Dm.5/157–16635 specimen (72.4% missingness). The percentage shown for each topology indicates the number of replicates in which that particular topology was recovered. **c**, As in **b**, but for the Javan rhinoceros (*R. sondaicus*). **d**, As in **b**, but for the black rhinoceros (*D. bicornis*).

Neg. contr. (blank)					NC	NC	NC	

The CGG reference number and the GNM specimen field number are reported for each specimen. B, bone; D, dentine; E, enamel. Extractions of enamel might include some residual dentine. Accordingly, both tissues are either listed separately (in cases with no collagen preservation) or together (in cases with collagen preservation). Open circles indicate no molecular preservation; closed circles indicate molecular preservation.

*Or the narrowest possible taxonomic identification achievable using comparative anatomy methods.
†Only collagens survive.

Extended Data Table 2 | Proteome composition and coverage

Aggregated data from different extraction methods and/or tissues from the same specimen are shown. In table cells that report two values separated by the | symbol, the left value refers to MaxQuant searches performed selecting unspecific digestion and the right value refers to MaxQuant searches performed selecting trypsin digestion. For those cells that include one value only, this value refers to MaxQuant searches performed selecting unspecific digestion. Final amino acid (aa) coverage, incorporating both the MaxQuant and PEAKS searches, is reported in the final column. Extended Data Table 1 provides the tissue sources per specimen, and the CGG and GNM specimen numbers.

*Supporting all peptides.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see [Authors & Referees](#) and the [Editorial Policy Checklist](#).

Statistical parameters

When statistical analyses are reported, confirm that the following items are present in the relevant location (e.g. figure legend, table legend, main text, or Methods section).

n/a Confirmed

- The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
- An indication of whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
- The statistical test(s) used AND whether they are one- or two-sided
Only common tests should be described solely by name; describe more complex techniques in the Methods section.
- A description of all covariates tested
- A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
- A full description of the statistics including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
- For null hypothesis testing, the test statistic (e.g. F , t , r) with confidence intervals, effect sizes, degrees of freedom and P value noted
Give P values as exact values whenever suitable.
- For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
- For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
- Estimates of effect sizes (e.g. Cohen's d , Pearson's r), indicating how they were calculated
- Clearly defined error bars
State explicitly what error bars represent (e.g. SD, SE, CI)

Our web collection on [statistics for biologists](#) may be useful.

Software and code

Policy information about [availability of computer code](#)

Data collection	Mass spectrometric data were acquired using the Xcalibur™ Software, controlling the Thermo Scientific™ LC-MS systems.
Data analysis	MaxQuant (versions 1.5.3.30, for main searches, and 1.6.0.16, for the dependent peptides searches) PEAKS (version 7.5) Geneious (version 5.4.4) ANGSD (version 0.915) ProSplign MAFFT Phangorn (R package) PHyML (version 3.1) MrBayes (version 3.2.6) CASAVA (version 1.8.2) PALEOMIX (version 1.2.6) AdapterRemoval (version 1.5) BWA backtrack (versions 0.5.10, 0.7.12 and 0.7.15) BWA aln (version 0.7.7) MarkDuplicate (http://picard.sourceforge.net/) HiSeq Control Software 2.0.12.0/RTA 1.17.21.3 SAMtools (version 0.1.19)

 deamidation.py (publicly available at: <https://github.com/dblyon/deamidation>)

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers upon request. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research [guidelines for submitting code & software](#) for further information.

Data

Policy information about [availability of data](#)

All manuscripts must include a [data availability statement](#). This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

All the mass spectrometry proteomics data have been deposited in the ProteomeXchange Consortium (<http://proteomecentral.proteomexchange.org>) via the PRIDE partner repository with the data set identifier PXD011008. Genomic BAM files used for Rhinocerotidae protein sequence translation and protein sequence alignments used for phylogenetic reconstruction are included in the compressed archive named "Supplementary_Data_1.zip".

Field-specific reporting

Please select the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Life sciences Behavioural & social sciences Ecological, evolutionary & environmental sciences

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	No sample size calculation was required. All available faunal specimen samples (23) were analyzed. Sample size includes numerous bone, dentine, and enamel samples, that therefore collectively allow us to estimate proteome survival in each of these tissues at the Dmanisi site.
Data exclusions	No data was excluded from the study.
Replication	Phylogenetic trees were reproduced using three different algorithms, and found consistent results (see Methods and SI). Proteomic results were replicated for several samples using repeated LC-MS/MS runs, and we observed consistent results within and between samples.
Randomization	Samples were injected in the LC-MS/MS system in randomised order.
Blinding	Ancient samples and control blanks were anonymised before the operator injected them in the LC-MS/MS system.

Palaeontology

Specimen provenance

Studied specimens derive from the Dmanisi archaeological/palaeontological site in Georgia (see Methods). Export of specimens to the Centre of GeoGenetics, Natural History Museum of Denmark, University of Copenhagen was regulated by approval of D. Lordkipanidze, Director of the Georgian National Museum and co-author.

Specimen deposition

Specimens are available upon request to E. Willerslev, E. Cappellini (Natural History Museum of Denmark), or D. Lordkipanidze, (Georgian National Museum).

Dating methods

No new dates obtained.

Tick this box to confirm that the raw and calibrated dates are available in the paper or in Supplementary Information.
